The ecological importance and diversity of pico/nanoplanktonic algae remains poorly studied in marine waters, in part because many are tiny and without distinctive morphological features. Amongst green algae, Mamiellophyceae such as *Micromonas* or *Bathycoccus* are dominant in coastal waters while prasinophytes clade VII, yet not formerly described, appear to be major players in open oceanic waters. The pigment composition of 14 strains representative of different subclades of clade VII was analyzed using a method that improves the separation of loroxanthin and neoxanthin. All the prasinophytes clade VII analyzed here showed a pigment composition similar to that previously reported for RCC287 corresponding to pigment group prasino-2A. However, we detected in addition astaxanthin for which it is the first report in prasinophytes. Among the strains analyzed, the pigment signature is qualitatively similar within subclades A and B. By contrast, RCC3402 from subclade C (*Picocystis*) lacks loroxanthin, astaxanthin, and antheraxanthin but contains alloxanthin, diatoxanthin, and monadoxanthin that are usually found in diatoms or cryptophytes. For subclades A and B, loroxanthin was lowest at highest light irradiance suggesting a light-harvesting role of this pigment in clade VII as in *Tetraselmis*.

**Key index words:** HPLC; phytoplankton; picoplankton; pigments; prasinophytes

The paraphyletic group of prasinophytes is an assemblage of free-living unicellular microalgae present in both marine and freshwater habitats (Leli-

aert et al. 2012). Molecular phylogenetic, ultrastructural, and biochemical approaches have helped taxonomists to reorganize gradually the group into new classes and clades (Guillou et al. 2004, Marin and Melkonian 2010, Subirana et al. 2013, Lemieux et al. 2014a). Currently, the prasinophytes are divided into nine groups known as clades I to IX based on phylogenetic analyses of the nuclear 18S (nuclear-encoded small subunit rRNA) gene (Fawley et al. 2000, Guillou et al. 2004, Viprey et al. 2008). These clades may correspond to true classes, or be composed of a small number of species or of environmental sequences only. For example, Chlorodendrophyceae (Massjuk 2006) known previously as prasinophytes clade IV was recently raised to the class level and added to the “core of chlorophytes” (Fucikova et al. 2014). Clade V corresponds to the order Pycnococcales with two major species, *Pseudoscourfieldia marina* and *Pycnococcus provasolii*, which are probably two forms of a single life cycle (Fawley et al. 1999, Guillou et al. 2004). Clades VIII and IX are composed entirely by environmental sequences without representatives in culture (Viprey et al. 2008). Clade II, previously corresponding to the order Mamiellales, was raised recently to the class level as Mamiellophyceae (Marin and Melkonian 2010) and contains three important genera of marine picophytoplankton: *Micromonas* (Butcher 1952), *Bathycoccus* (Eikrem and Thronsen 1990), and *Ostreococcus* (Chrétiennot-Dinet et al. 1995).

In coastal waters, Mamiellophyceae appear largely dominant, especially within the picoplankton, with the genus *Micromonas* making the highest contribution and followed to a lesser extent by *Bathycoccus* (Thronsen and Kristiansen 1991, Not et al. 2004, Collado-Fabri et al. 2011, Balzano et al. 2012). contrast, in the open ocean, another group of prasinophytes, clade VII, with cell size in the 3–5  $\mu\text{m}$  range, has been found to make an important contribution to the picoplankton community in regions such as the Equatorial Pacific and Mediterranean Sea (Moon-van der Staay et al. 2000, Viprey et al. 2008, Shi et al. 2009). The distribution of clade VII in typically oceanic mesotrophic waters makes this an interesting group. Prasinophyte clade VII contains several cultured strains mostly from tropical and subtropical waters but also from temperate regions, although it has not been described formerly yet. Guillou et al. (2004) divided this group into three well-supported subclades A, B and C, the latter being formed by *Picocystis salinarum*, a small species found in saline lakes (Lewin et al. 2000, Roesler et al. 2002, Krienitz et al. 2012).

Traditionally, pigment signature has been used to determine the taxonomy of algae groups present in the water column (Jeffrey et al. 2011). This approach has been largely superseded by molecular approaches (Liu et al. 2009) but pigments remain an important phenotypic characteristic that allowed to point out the importance of green algae in specific regions of Pacific Ocean, Mediterranean Sea, or Arctic Ocean (Obayashi and Tanoue 2002, Miki et al. 2008, Gutiérrez-Rodríguez et al. 2010, Coupel et al. 2014). The study of pigments in different types of prasinophytes has revealed a diversity of photosynthetic signatures in this group. Prasinophytes can be divided into three major groups based on their carotenoid composition (Egeland et al. 1997, Garrido et al. 2009). Group 1 contains the basic set of carotenoids present in Chlorophyceae: neoxanthin, violaxanthin, lutein, zeaxanthin, antheraxanthin, and  $\beta$ - $\beta$ -carotene. Group 2

consists of the basic set of carotenoids plus loroxanthin (2A) and siphonaxanthin (2B). Group 3 contains prasinoxanthin (3A) and uriolide, micromonal, micromonol, and dihydrolutein (3B) in addition to the main pigments found in group 1 (Jeffrey et al. 2011).

Within clade VII, only three strains have been analyzed until now: two isolates of *Picocystis salinarum* (subclade C) from saline lakes (Lewin et al. 2000, Roesler et al. 2002) and the marine strain RCC287 (subclade A; Latasa et al. 2004). A large number of clade VII strains are available from the Roscoff Culture Collection (<http://roscoff-culture-collection.org/>) originating from a range of environments. The aim of this study was to determine the phenotypic characteristics of this important group of marine green algae by analyzing the pigment composition of 14 strains belonging to the three subclades (A, B, C) of prasinophytes clade VII isolated from a range of oceanic location and depths (Table 1). We also assessed the effect of three light irradiances on pigment composition for a subset of these strains.

Twelve strains belonging to clade VII (Table 1) were grown at 22°C in 25 cm<sup>2</sup> culture flasks with 50 mL of K seawater medium (Keller et al. 1987) under 140  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$  in continuous light. Two other strains, added later, were grown under the same conditions except for light (100  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$  in 12:12 Light:Dark cycle). A subset of nine strains was also grown at two other light levels (14 and 65  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ ). All strains were acclimated to the light conditions during at least five generations. Prior to sample collection, cell concentration was determined by flow cytometry using a Becton Dickinson Accuri C6. Approximately, 50 mL of cul-

\*Values reported by Latasa et al. 2004

tures were collected in late exponential or early stationary phase by filtration onto glass fiber GF/F filters (Whatman, Maidstone, UK) without vacuum. The total time for filtration did not exceed 10 min and filters were removed as soon as the passage of liquid trough it was undetectable. Total volume filtered was recorded. Filters were protected from light at all processing stages, immediately frozen in liquid nitrogen and stored at  $-80^{\circ}\text{C}$ . Pigments were analyzed within 1 month. Frozen filters were extracted with 3 mL of 90% acetone in screw cap glass tubes with polytetrafluoroethylene (PTFE) lined caps placed in an ice-water bath. After 15 min, filters were homogenized using a stainless steel spatula for filter grinding. Tubes were placed in an ultrasonic bath with water and ice for 5 min. The slurries were then centrifuged 5 min at 4,500 rpm and supernatants filtered through 13 mm diameter polypropylene syringe filters (MS PTFE, 0.22  $\mu\text{m}$  pore size) to remove cell and filter debris. Before injection, 1 mL of each sample extract was added with 0.4 mL of Milli-Q water to avoid peak distortion. Pigments extracted from clade VII strains were analyzed using a modification of Zapata et al. (2000) method, described by Garrido et al. (2009) to improve the separation of loroxanthin and neoxanthin (Table S1 in the Supporting Information). Pigment extracts of RCC3402 (*Picocystis*) were also analyzed employing a polymeric octadecyl silica column as described by Garrido and Zapata (1997). All graphs and analyses were performed with the R software using the ggplot2 and FactoMineR libraries (R Development Core Team 2013).

Intracellular chlorophyll (Chl) *a* content ranged from 4 to 26  $\text{fg} \cdot \text{cell}^{-1}$  in most strains except for RCC996 (VIIA) and RCC3402 (*Picocystis*—clade VIIC) for which it was much higher (Table 2). This range agreed with values previously determined for marine microalgae in the same size range (Simon et al. 1994). More recently, in a field survey, Giovangnetti et al. (2013) found 20–60  $\text{fg} \cdot \text{cell}^{-1}$  in nanophytoplankton ( $>3 \mu\text{m}$ ). Brunet et al. (2006) estimated a range of 17–168  $\text{fg} \cdot \text{cell}^{-1}$  in picoeukaryotes from the deep chlorophyll maximum (DCM) and finally, Durand et al. (2002) as well as Not et al. (2004) reported 25  $\text{fg} \cdot \text{cell}^{-1}$  in the pico-planktonic species *Micromonas pusilla*.

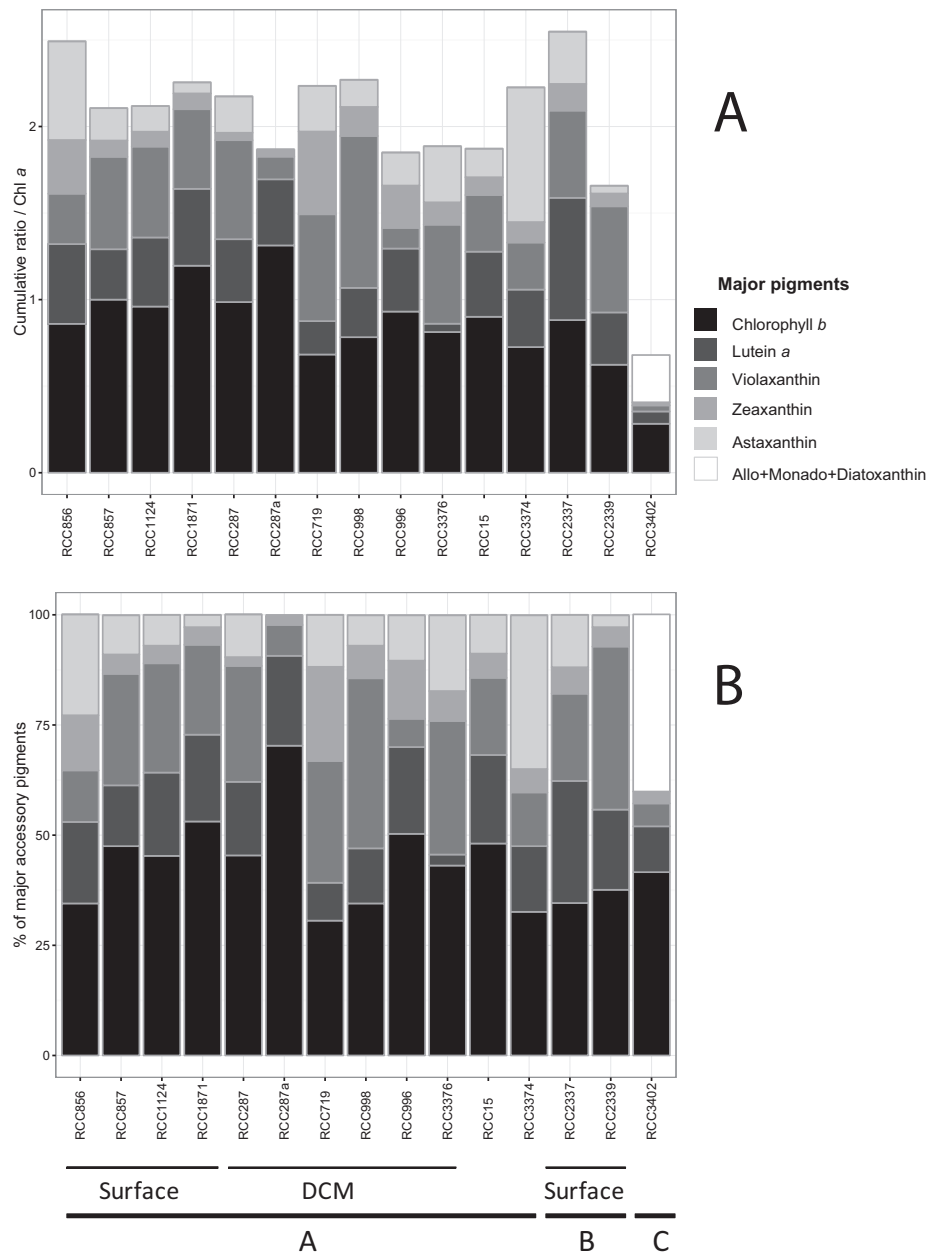

All the prasinophytes clade VIIA and B analyzed here showed a very similar pigment composition (Table 2). It did not seem to change drastically between subclades A and B nor with the depth of isolation (Fig. 1). This composition is similar to that reported for RCC287 by Latasa et al. (2004) corresponding to pigment group prasino-2A. We did not observe strong differences (Fig. 1; Table 2) with the data of Latasa et al. (2004): in particular, the ratios obtained for zeaxanthin and lutein were very similar in both studies despite the slight difference in light levels (100 vs. 140  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$  in our

study): zeaxanthin, 0.042 (w/w) versus 0.043 (w/w); and lutein, 0.382 (w/w) versus 0.363 (w/w). However, their study used a less resolutive method and did not report the presence of loroxanthin and astaxanthin in RCC287. For loroxanthin, this is probably due to the coelution of this pigment with neoxanthin in the analytic method employed by these authors.

In our study, only RCC1124 and RCC1871 (both from sub-clade A) did not contain loroxanthin within strains belonging subclades A and B (Table 2). Violaxanthin and lutein were the most abundant carotenoids for subclades A and B. Astaxanthin came as third for most other A and B strains except for RCC1871 (subclade A) and RCC2339 (subclade B) for which it was neoxanthin and  $\beta$ - $\beta$ -

carotene, respectively. *Picocystis* (RCC3402, clade VIIC) had a clearly distinct carotenoid profile compared to subclades A and B. It did not contain loroxanthin, astaxanthin, and antheraxanthin but instead diatoxanthin, alloxanthin, and monadoxanthin (Fig. 1; Table 2). For this strain,  $\beta$ - $\beta$ -carotene, monadoxanthin, and diatoxanthin were the most abundant carotenoids, respectively (Fig. 1; Table 2) and the ratio of accessory pigments to Chl *a* was much lower than in clades VIIA and B (Fig. 1). The presence in *Picocystis* of these pigments usually found in cryptophytes or diatoms (Takaichi 2011), which are parts of the so-called red lineage (by opposition to the green lineage to which clade VII belongs, Falkowski et al. 2004), was also reported by

FIG. 1. (A) Cumulative ratios of Chl *b* and five major carotenoids (lutein *a*, violaxanthin, zeaxanthin, astaxanthin, alloxanthin + monadoxanthin + diatoxanthin) to Chl *a* for 14 strains of prasinophytes clades VII at 140 or 100  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$  (see Table 2). Strains are ordered by subclades (A, B, C) and depth of isolation (surface, deep chlorophyll maximum-DCM). RCC287a correspond to the composition reported by Lataša et al. (2004) for this strain. (B) Same as A, but with relative abundance of Chl *b* and five major carotenoids.

Lewin et al. (2000) and Roesler et al. (2002) as well as found in *Coccomyxa*, a green alga belonging to the Chlorophyceae (Crespo et al. 2009).

We analyzed the influence of irradiance (14, 65 and 140  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ ) on pigment composition of nine strains of prasinophytes VIIA and B (Fig. 2; Table S2 in the Supporting Information). Accessory Chls and carotenoids involved in light harvesting tend to increase relative to Chl *a* at low light, while photoprotective carotenoids increase at high light (Schlüter et al. 2000, Henriksen et al. 2002, Brunet et al. 2011). In our study, Chl *b* ratios increased slightly at low light, as expected, except for RCC3376 that showed a very slightly lower ratio at low light than at high light (0.78 vs. 0.81; Fig. 2; Table S2). A similar slight decrease was also observed by Garrido et al. (2009) for the green alga *Tetraselmis suecica*.

The increase at low light of neoxanthin,  $\beta$ - $\epsilon$  carotene, and loroxanthin points to a light harvesting role for these pigments in most of the strains (Fig. 2; Table S2). The changes can be subtle, as in the case of neoxanthin or drastic, as observed for loroxanthin (Fig. 2). Neoxanthin has been found to be associated with light harvesting complexes in the Mamiellophyceae *Mantoniella squamata* (Wilhelm and Lenarz-Weiler 1987). A major light harvesting role could be suggested for loroxanthin in clades

VII A and B in agreement with that observed by Garrido et al. (2009) in another Chlorophyta, *Tetraselmis*. Interestingly, two strains lacking loroxanthin (RCC1124 and RCC1871) have been isolated from temperate North Atlantic Ocean waters in contrast to the other strains from subclade A, which originate from tropical waters (Table 1).

The increase in astaxanthin (from 2- to 4-fold depending on the strains) with light intensity suggests that this carotenoid has a photoprotective role (Fig. 2), as previously demonstrated in the Chlorophyceae *Haematococcus pluvialis* (Wang et al. 2003, Gao et al. 2012). Among all strains, RCC3374 showed the most impressive accumulation of astaxanthin, which contributed up to 42% of the total carotenoid pool under high light conditions (Fig. 2). In comparison, *H. pluvialis* can accumulate 86%–90% of astaxanthin in the total carotenoid pool after 16 d cultures under stress conditions (Sarada et al. 2002).

The photoprotective role attributed to lutein (Jahns and Holzwarth 2012) seems to happen also in these species. Its contribution to total carotenoids increased sharply from low to medium light and stabilized at the highest irradiance (Fig. 2; Table S2). Such increase under high light conditions has been previously reported by Böhme et al. (2002) in the Mamiellophyceae *M. squamata*.

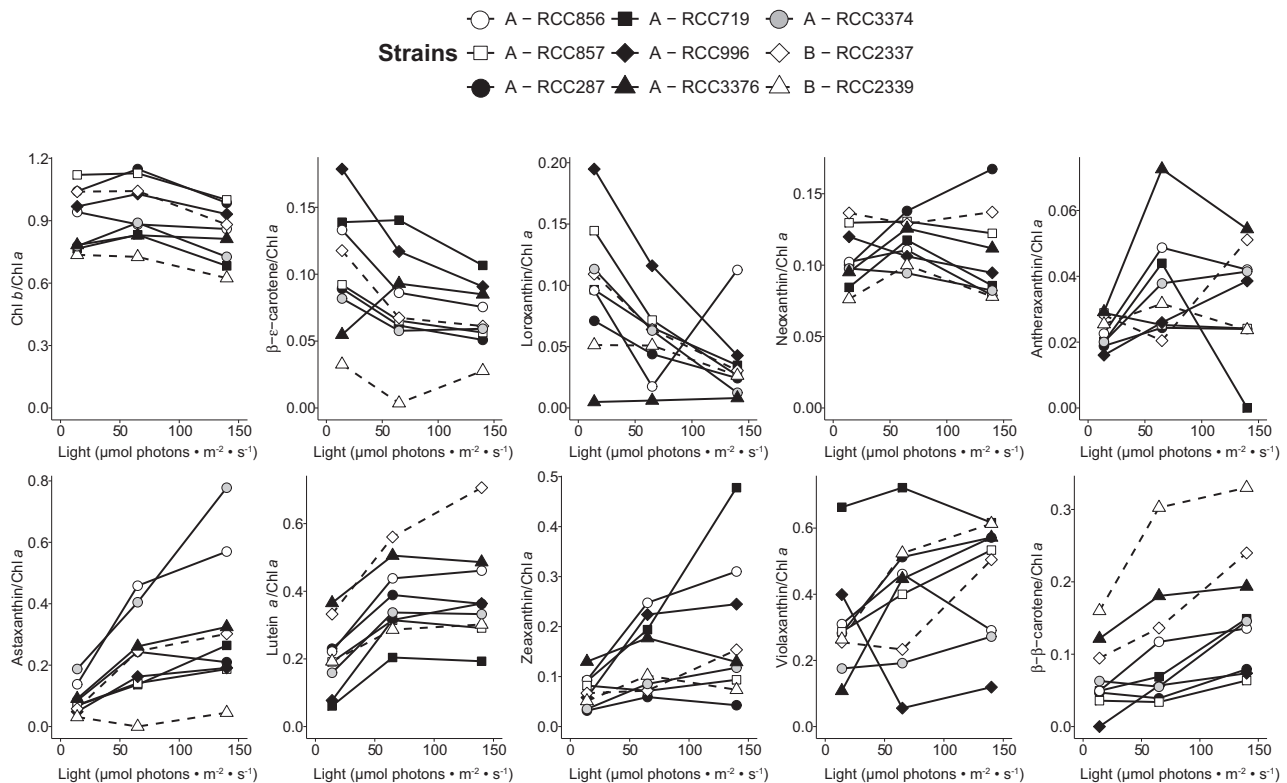

FIG. 2. Change in pigment to Chl *a* ratios for Chl *b* and nine major carotenoids in nine strains of prasinophytes clade VII under three light intensities. Solid lines correspond to subclade VIIA and dashed lines to VII B. Open symbols correspond to surface strains, closed ones to deep chlorophyll maximum strains, and grey to unknown depth of isolation.

These authors suggested that lutein played an important role as intermediate of biosynthesis for light-harvesting pigments after light shifts from HL to LL. This role was coherent with its loose binding to the LHC apoprotein, also observed for the violaxanthin cycle (VAZ) carotenoids. However, lutein and loroxanthin are xanthophylls derived from  $\beta$ - $\epsilon$  carotene, and both have also been suggested also to take part in photoprotective mechanisms (non-photochemical quenching, NPQ) to prevent photo-oxidative damage in high light conditions in the green alga *Chlamydomonas reinhardtii* (Niyogi et al. 1997).

As for lutein, the content of the photoprotective xanthophyll cycle involving violaxanthin, antheraxanthin, and zeaxanthin (VAZ cycle) relative to Chl *a* increased from low to medium light and then stabilized (Fig. 2; Table S2). However, the evolution of individual pigments differed among strains. For example, zeaxanthin did not change much in RCC287 and RCC857 while it increased several fold in other strains (e.g., RCC719, Fig. 2).

A relationship between strain origin and pigment composition is unlikely according to a principal component analysis based on pigments to Chl *a* ratios (Fig. 3). The first two components explained more than 50% (dimension 1 and 2, 33.1% and 20.4%, respectively) of the variance. Pigments contributing positively to dimension 1 included some which may have a photoprotective role (lutein, zeaxanthin, antheraxanthin, and astaxanthin) while pigments suggested to be involved in light harvesting, such as loroxanthin, contributed negatively to this axis. Pigments with moderate response to light, such as Chl *b* and neoxanthin, contributed to dimension 2. Strains distributed along dimension 1 according to the light treatment, irrespectively of their subclade, latitude, or depth of isolation (surface vs. DCM). The use of HPLC data to assess the role of individual pigments as light-harvesting or photoprotective must be considered with caution. Photoacclimation processes operate at different scales (from seconds to several days) and pigment changes are influenced by multiple factors (genetics, ecology, physiology). Despite all this, some common patterns can be found when pigment data are given in terms of their ratios to Chl *a*. Light-harvesting pigments and Chl *a* content increase under low irradiance and tend to covary under variable light conditions. In turn, photoprotective pigments are synthesized under light stress and increase their ratios to Chl *a* in higher light irradiance (Brunet et al. 2011). The behavior of pigments analyzed in clade VII resembled that expected for light-harvesting or photoprotective ones, but without a more complete dataset (biochemistry, photosynthetic dynamics, etc.), this cannot be stated unambiguously. The discovery of loroxanthin (a putative light harvesting pigment) and astaxanthin (with a suggested photoprotective role) in prasinophytes clades VIIA and B prompts

the need to reexamine the pigment composition of other members of this diverse and ancient group using improved analytical protocols.

Recent phylogenetic results pointed clade VII A/B as a sister group of the core of Chlorophyta (Guillou et al. 2004, Leliaert et al. 2012, Lemieux et al. 2014a,b). The presence of astaxanthin as in core Chlorophyta while it is absent in other prasinophytes may reflect another common feature between clade VII and core Chlorophyta. Moreover, while Guillou et al. (2004) included *Picocystis* into

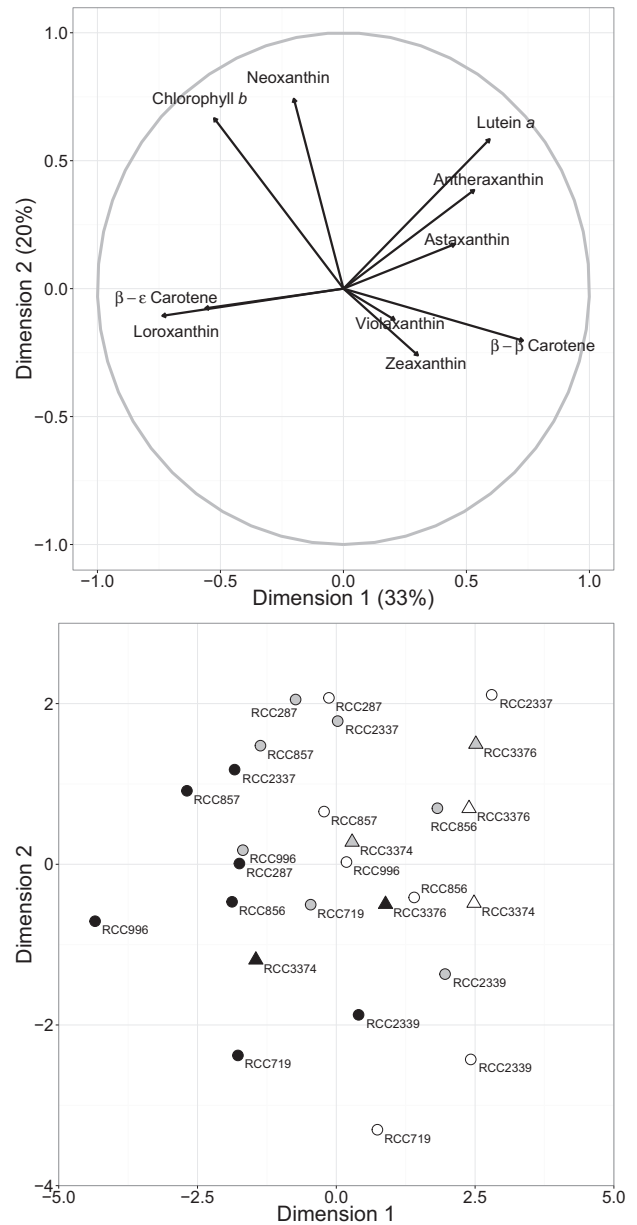

FIG. 3. Principal component analysis using the pigment to Chl *a* ratios as variables for the strains grown at three light levels (Table S2). Top: variables; bottom: samples. Circles correspond to clade VIIA and triangles to clade VIIB. Closed symbols correspond to low light, grey symbols to medium light, and open symbols to high light.

clade VII based on the phylogenetic analysis of 18S rRNA gene, the recent analysis of chloroplast genomes (Lemieux et al. 2014a) has shown widely divergent traits between *Picocystis* and subclade VIIA. The divergent carotenoid composition of *Picocystis* (absence of loroxanthin, astaxanthin, and antheraxanthin, and confirmation of the presence of red lineage pigments such as diatoxanthin and monadoxanthin) reinforces these phylogenetic analyses and point out the interest of pigments as phenotypic markers.
